STI Working Paper Series

The Working Paper series of the OECD Directorate for Science, Technology and Industry is designed to make available to a wider readership selected studies prepared by staff in the Directorate or by outside consultants working on OECD projects. The papers included in the series cover a broad range of issues, of both a technical and policy-analytical nature, in the areas of work of the DSTI. The Working Papers are generally available only in their original language – English or French – with a summary in the other.

Comments on the papers are invited, and should be sent to the Directorate for Science, Technology and Industry, OECD, 2 rue André-Pascal, 75775 Paris Cedex 16, France.

The opinions expressed in these papers are the sole responsibility of the author(s) and do not necessarily reflect those of the OECD or of the governments of its member countries.

ABSTRACT

Efforts to reduce greenhouse gas (GHG) emissions which are linked to the global climate system such as the Kyoto Protocol might fail, if emission-restricted states relocate their carbon-intensive production activities to non-restricted countries where the primary production factors depend on more GHG-intensive sources. Such a relocation process and increased 'carbon trade' appear to be contrary to the GHG reductions envisioned in international agreements. This study addresses the issue of carbon embodiments in trade using internationally-comparable OECD data sources (Input-Output, Bilateral Goods Trade and CO₂ emissions) for 41 countries/regions by 17 industries. Simulation results under base case scenarios for the mid-1990s and the early 2000s suggest that "trade deficits" of CO₂ emissions are observed in 21 OECD countries in the early 2000s and that for 16 countries, the magnitude of the trade deficit increased in the late 1990s. While a third (860 Mt CO₂) of the global increase in production-based emissions took place within the non-OECD economies in the late 1990s, more than half of the consumption-based emission (1550 Mt CO₂) is still attributable to OECD consumption. The sensitivity simulations imply that an increase in global trade intensity has an increasing impact on embodied emissions while technology transfers from carbon-intensive countries to high carbon-intensive countries reduce global emissions and carbon trade gaps.

LA MESURE DES QUANTITÉS DE CO₂ INCORPORÉES DANS LES ÉCHANGES INTERNATIONAUX : DONNÉES PROVENANT DE LA BASE DE DONNÉES HARMONISÉE DES ENTRÉES-SORTIES ET DU COMMERCE BILATÉRAL

RÉSUMÉ

Les efforts visant à réduire les émissions de gaz à effet de serre (GES) liées au système climatique mondial, notamment dans le cadre du Protocole de Kyoto, risquent d'échouer si les États où s'appliquent des limitations des émissions délocalisent leurs activités de production à forte intensité de carbone vers des pays où ces restrictions ne sont pas imposées et où les facteurs de production primaire sont tributaires de sources qui émettent plus de GES. Ce processus de délocalisation et l'augmentation des 'échanges de carbone' vont à l'encontre des réductions des GES envisagées dans les accords internationaux. Cette étude aborde la question des quantités de carbone incorporées dans les échanges en utilisant des sources de données de l'OCDE comparables au plan international (entrées-sorties, commerce bilatéral et émissions de CO₂) concernant 41 pays/régions et 17 branches d'activité. Dans les résultats des simulations effectuées avec des scénarios de référence couvrant le milieu des années 1990 et le début des années 2000, on observe des "déficits des échanges" d'émissions de CO₂ dans 21 pays de l'OCDE au début des années 2000 et, s'agissant de 16 pays, un accroissement du solde négatif de ces échanges à la fin des années 1990. Si un tiers (860 Mt de CO₂) de l'augmentation mondiale des émissions dues à la production a été produit dans des économies non membres de l'OCDE à la fin des années 1990, plus de la moitié des émissions associées à la consommation (1550 Mt de CO₂) sont encore imputables à la consommation de la zone OCDE. Les simulations des sensibilités laissent supposer qu'un accroissement de l'intensité des échanges mondiaux a un effet à la hausse sur les émissions incorporées, tandis que les transferts de technologie des pays moins émetteurs de carbone vers les pays gros émetteurs réduisent les émissions mondiales et les soldes négatifs des échanges de carbone.

EXECUTIVE SUMMARY

Efforts such as the Kyoto Protocol to mitigate greenhouse gas (GHG) emissions will be less effective in reducing global emissions of GHG, if they lead countries with emission commitments to relocate their carbon-intensive production activities to countries without such commitments, particularly if production in these latter countries is GHG-intensive. Concern about such “carbon leakage” is high in the run-up to an agreement on the post-2012 climate regime.

Following the previous OECD study by Ahmad and Wyckoff (2003), this study measures the international transfer effects of CO₂ emissions (fuel combustion based) using an updated internationally-comparable economic and energy database. The number of target countries has been increased to 41 countries/regions so that more than 90% of global GDP is now covered. The major findings of our simulation results are as follows (Table 1).

- Accounting for emissions in terms of production and in terms of consumption yield very different results. While one-third of global increase in production-based CO₂ emissions (860 Mt CO₂) took place within the OECD economies (total of 30 members) in the late 1990s, more than half of the global increase in consumption-based emission (1 550 Mt CO₂) is attributable to OECD consumption.
- The acceleration of globalisation, such as international outsourcing and fragmenting of production processes, increased the carbon embodied in international trade in the late 1990s. Among the carbon trade deficit countries in the mid-1990s (28 countries, Table 1), the magnitude of carbon trade deficit (net carbon imports / production-based emissions) has increased in 17 countries (Belgium, Germany, Hungary, Ireland, Italy, Japan, Luxembourg, Netherlands, Spain, Sweden, Switzerland, United Kingdom, United States, Argentina, Brazil, Israel, and Singapore).
- Net trade deficits in the embodied CO₂ trade are observed in 21 OECD countries in 2000. The G6 OECD countries (France: -134 Mt CO₂; Germany: -147 Mt CO₂; Italy: -127 Mt CO₂; Japan: -312 Mt CO₂; United Kingdom: -196 Mt CO₂ and United States: -858 Mt CO₂) accounted for 91% of the CO₂ trade deficit. The consumption-based emissions of these G6 countries exceed production-based emissions by 35% for France, 18% for Germany, 30% for Italy, 27% for Japan, 37% for United Kingdom, and 15% for United States respectively in 2000.
- 75% of the non-OECD’s CO₂ trade surplus is attributable to five major non-OECD countries: Russia (586 Mt CO₂), China (387 Mt CO₂), Indonesia (64 Mt CO₂), India (56 Mt CO₂), and South Africa (55 Mt CO₂).
- Additional sensitivity simulations suggest that an increase in trade intensity increases emissions embodied in international trade, whereas technology transfers from less carbon-intensive countries to more carbon-intensive countries reduce aggregate global emissions as well as carbon trade gaps.

Our simulation results suggest that future policy discussions on global emissions of GHG need to consider inter-country frameworks rather than just setting goals for individual countries as if economies were unconnected by trade. Thus, multi-sectoral inter-country models have a great potential to provide effective indicators for policy discussions of post-Kyoto.

1. INTRODUCTION

The reduction of emissions of greenhouse gasses (GHG), notably CO₂, is a goal which has gained worldwide consensus as part of the desired mitigation of global warming processes within the framework of the United Nations Framework Convention on Climate Change (UNFCCC). As of October 2008, the Kyoto Protocol has been ratified by more than 180 countries. The ratified countries have tried to reduce CO₂ emissions by implementing various energy related-policies such as support for the development of renewable energy sources and energy-efficient technologies, implementation of various regulations for energy-intensive activities, and establishment of carbon-trading markets (*e.g.* the EU Emission Trading Scheme), in addition to other activities in arenas including forestry, agriculture, and waste management.

Global emissions, however, have been consistently increasing, most notably in the states designated as non-Annex I countries (Figure 1) by the UNFCCC. The global agreement under UNFCCC's Kyoto Protocol has been argued on the anticipated limitation of global reduction in emissions and the possibilities of carbon leakages through international trade. Global CO₂ emissions are likely to continue to increase if the more strongly carbon-restricted Annex I countries relocate their carbon-intensive production activities to less-strictly constrained countries which have lower environmental standards. This relocation process is likely to lead to an increase in overall global GHG emissions.

Figure 1. Greenhouse gas emissions (territorial-base)

Sources: IEA CO₂ emissions from Fuel Combustion and OECD Environmental Outlook 2008.
 OECD Countries: Current 30 members, BRIC: Brazil, Russia, India, and China.

Most of the CO₂ emissions from fuel combustion are directly correlated to the level of carbon-intensive activities, such as electricity generation, production of chemicals and basic metal products, and consumption of transport fuels. In terms of these direct production-based emissions, 37.1% of global CO₂ emissions in 2006 originate from electricity and heat production, 23.0% from transport, and 19.6% from manufacturing industries/construction (CO₂ Emissions from Fuel Combustion Edition 2008, IEA).

The consumption-based emissions, on the other hand, are accounted for by demand of goods and services by households and firms. The net carbon trade balances could even become negative in countries with monetary trade surpluses, if those countries import highly-carbon-intensive goods and export products that are less carbon-intensive. Such possibilities may be explored through quantifying the complex

interdependencies among industries, domestic and foreign final demands. Practical estimations of such effects may be found through analysing Input-Output (I-O) databases. Many studies have in fact applied I-O analysis to measure the emissions embodied in international trade. Most of such efforts are applications which employ a single-country framework, such as Machado *et al.* (2001) for Brazil, Munksgaard and Pedersen (2001) for Denmark, Sanchez-Choliz and Duarte (2004) and Santacana *et al.* (2008) for Spain, Mongelli *et al.* (2006) for Italy, and Schoer *et al.* (2007) for Germany. The gap between production-based and consumption-based emissions has become even larger in the years since 2000 (Santacana *et al.*, 2008).

As cross-border supply chains have become more prevalent in the global economy, feedback effects and fragmented production processes must be taken into account by using a multinational framework to measure the emissions embodied in trade. Evidence for this position can be found by examining the import contents embodied within exported goods and services – an indicator for the transnational fragmentation introduced by a globalising economy – which increased in most countries during the late 1990s (Figure 2).

Figure 2. Import contents of exports by country (Input-Output based)

Note: Import contents of countries' exports is calculated as $u * Am * (I-Ad)^{-1} * X/X_k$ where Am and Ad are the input-output coefficient for imported and domestic goods respectively; u denotes a vector each of whose components is unity, X is a vector of exports and X_k is total country exports. For example, an import content of exports of 20% indicates that 20% of the exports in a country are directly and indirectly based on intermediate inputs that have been imported.
Source: OECD Input-Output Database (De Backer and Yamano, 2007).

Multinational I-O analysis, however, requires highly-harmonised economic datasets (*e.g.* Peters, 2007), including appropriate national I-O tables, adequate data on bilateral trade in goods and services, and some other components of national accounts. Adequate databases are not often published by national statistical offices. The preceding examples have devoted significant efforts to the gathering and developing of comparable multinational data sources, including Nakano *et al.* (2008) for the nine East Asian countries, Shui and Harris (2005) for United States-China, Ackerman *et al.* (2007) for Japan-US, and Hayami and Nakamura (2007) for Canada-Japan.

For OECD economies, Wyckoff and Roop (1994) measured the emissions embodied in the inputs of manufacturing goods using the I-O tables of six OECD countries (Canada, France, Germany, Japan, United Kingdom and United States) and indicated that an equivalent of 13% of the total carbon emissions are embodied within imported goods in the mid-1980s.

Ahmad and Wyckoff (2003) then expanded the country coverage using highly harmonised data on bilateral trade in goods alongside the I-O tables of 24 countries for years around 1995 in order to measure the CO₂ embodiments in international trade. Their results suggest that the emissions required for domestic

consumption are higher than the emissions given off by domestic production within the OECD as a whole. Particularly, the emissions associated with domestic consumption are significantly larger than those associated with domestic production in those larger OECD countries where less-carbon-intensive facilities have been introduced into electricity-generation sectors.

Building on previous analyses based on OECD data sources, we have carried out carbon-embodiment analyses which rely on the following contributions:

1. Greater accuracy in calculation through the inclusion of a more harmonised input-output database which also has wider coverage on target countries.
2. Sensitivity analyses of counterfactual simulations, including exploration of the impacts of improved energy efficiency as well as of changes in import dependencies.

The structure of this paper is as follows. The next section describes the proposed model for measuring CO₂ embodiments in international trade. The data sources and findings from the harmonised database are described in section 3. The simulation cases are described in section 4 with detailed comparison of the simulation results. In the last section, we conclude by suggesting how our calculations on production and consumption-based emissions can be useful for further policy discussions. The details of database harmonisation and simulation results are also provided in the annexes.

2. MODEL

2.1 Overview

In order to accurately estimate the total effects of international CO₂ trade, the single-country model framework has to be extended to a more complicated multinational framework. Employing simulation methodology similar to that of Ahmad and Wyckoff (2003), the production and consumption-based emissions of CO₂ are explicitly separated in each country within our model.

Imported CO₂ is defined in this paper as the emissions embodied in the imports used for intermediate and final consumption. The emission factor of each country is simultaneously determined under the conditions of interdependent relations between import trade partners. The exported CO₂ is also solved through rigorous iterative procedures because a part of CO₂ imported to a country is obviously exported back. Thus the eventual trade balances of imported and exported CO₂ emissions are determined by the complex conditions of existing natural resources, energy efficiencies of production facilities, import penetration ratios and the combinations of trade partners.

The domestic consumption of embodied CO₂ emissions is defined as the emissions embodied within household and government final consumption, investment, and the changes in inventory. This includes direct and indirect effects from goods, accounting for the differing degrees to which the constituents of utilised goods are produced domestically and/or internationally.

On the other hand, the production-based CO₂ emission is defined simply as the CO₂ emitted within each country. Measuring the production-based CO₂ is easier than capturing the total emissions of consumption basis because the calculation of consumption-based emissions requires the detailed

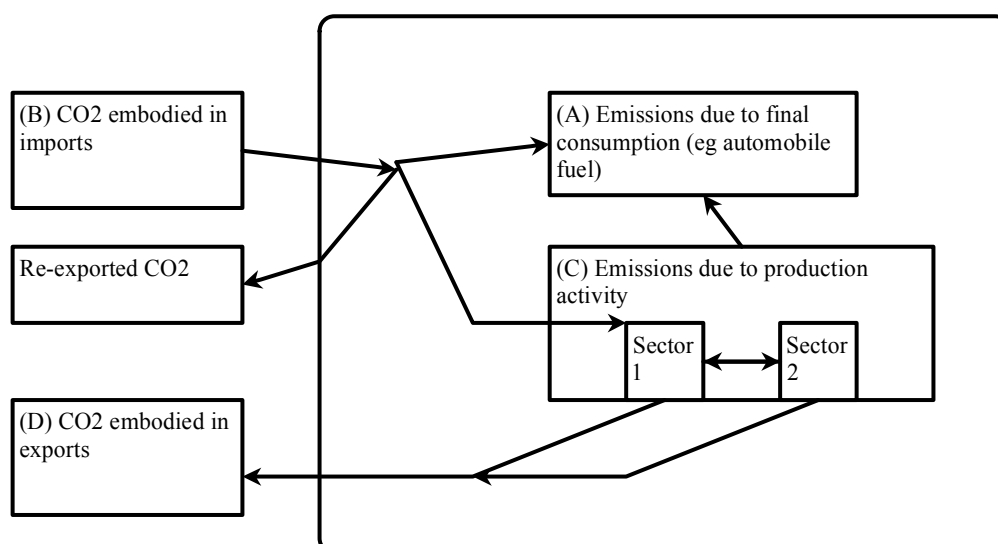

specification of inter-industry and international trade structures (See Figure 3 for an example of CO₂ embodied in trade).

The consumption-based and production-based emissions measures, taking into account CO₂ embodied in international trade, can be subdivided into the following components:

a) Consumption-based emissions = Emissions regarding the domestic final demand (A)
 + Emissions embodied in imports (B)
 + Emissions of production activities (C)
 - Exports (D).

b) Production-based emissions = Emissions regarding domestic final demand (A)
 + Emissions embodied in exports (C)

Figure 3. Emissions embodied in international trade for a single country

2.2 Mathematical specification

The following equations detail the mathematical formulations for calculating the CO₂ emissions of domestic consumption, of production, and of those embodied in international trade.

The CO₂ associated with domestic consumption includes the emissions induced domestically by domestic final demand as well as the emissions in trade partners that are indirectly embodied in imports (whether intermediate or final). The emissions induced by domestic consumption of country α are defined as the product of direct emission factors and the output induced by domestic final demand as follows:

$$(1) \mathbf{e}_\alpha (\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \mathbf{f}_\alpha$$

where \mathbf{e}_α is a $1 \times N$ industries vector of emission factors (CO₂ emissions per unit of domestic output in USD), $(\mathbf{I} - \mathbf{A}_\alpha^D)^{-1}$ is the ordinary $N \times N$ Leontief inverse matrix, and \mathbf{f}_α is the $N \times 1$ vector of domestic final consumption of domestically produced goods. The domestic final consumption refers to the sum of

household final consumption, general government final consumption, changes in inventories, gross fixed-capital formation and valuables by industry.

On the other hand, the emissions embodied in imported goods are determined by the emission factors of trade partners. The emission factors of goods imported from country β is written as

$$(2) \mathbf{e}_\beta^* \left[\mathbf{A}_{\alpha,\beta}^M (\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \mathbf{f}_\alpha + \mathbf{nm}_{\alpha,\beta} \right]$$

where \mathbf{e}_β^* is a $l \times N$ industries vector of the trade-embodied CO₂ emission factors of exports from country β , $\mathbf{A}_{\alpha,\beta}^M$ is the input-output coefficient of goods imported to country α from country β , and \mathbf{nm} is a $N \times l$ vector of non-comparable imports (*i.e.* imports directly for domestic final consumption) from country β . $\mathbf{A}_{\alpha,\beta}^M$ and \mathbf{nm} are simply separated from the intermediate and final demand matrices of total imported goods using the corresponding import share from the bilateral trade database, because the intercountry input-output structures of intermediate and final demand are not available in the ordinary non-competitive input-output table framework.

Summing the emissions embodied in the imports from all trade partners and emissions induced by domestic industry, the total emissions associated with country α , measured on a consumption basis, $\mathbf{z}_\alpha^{\text{DC}}$, is written as

$$(3) \mathbf{z}_\alpha^{\text{DC}} = \mathbf{e}_\alpha (\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \mathbf{f}_\alpha + \sum_{\beta}^W \mathbf{e}_\beta^* \left[\mathbf{A}_{\alpha,\beta}^M (\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \mathbf{f}_\alpha + \mathbf{nm}_{\alpha,\beta} \right] + e^{fd} \mathbf{f}_\alpha$$

where W is number of trade partners, and $e^{fd} \mathbf{f}_\alpha$ is the emissions regarding fuel combustions regarding final consumption which are non-tradable emissions.

Since the trade-embodied emission factors are simultaneously determined with the imports, the emission factor by sector in each country is calculated as a result of numerical iterations. The converged CO₂ emission factor and emissions embodied in exports are simultaneously determined by

$$(4) \mathbf{e}_\alpha^* = \mathbf{z}_\alpha^{\text{EX}} \left(\hat{\mathbf{f}}_\alpha^{\text{ex}} + \sum_{\beta}^W \hat{\mathbf{f}}_{\alpha,\beta}^{\text{rx}} \right)^{-1}$$

and

$$(5) \mathbf{z}_\alpha^{\text{EX}} = \mathbf{e}_\alpha (\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \hat{\mathbf{f}}_\alpha^{\text{ex}} + \sum_{\beta}^W \mathbf{e}_\beta^* \left[(\mathbf{A}_{\alpha,\beta}^M (\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \hat{\mathbf{f}}_\alpha^{\text{ex}} + \hat{\mathbf{f}}_{\alpha,\beta}^{\text{rx}} \right],$$

where $\hat{\mathbf{f}}_\alpha^{\text{ex}}$ and $\hat{\mathbf{f}}_{\alpha,\beta}^{\text{rx}}$ are the diagonal matrices of exports and re-exports from trade partner country β to α , $(\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \hat{\mathbf{f}}_\alpha^{\text{ex}}$ is the domestically emitted CO₂ and $\mathbf{A}_{\alpha,\beta}^M (\mathbf{I} - \mathbf{A}_\alpha^D)^{-1} \hat{\mathbf{f}}_\alpha^{\text{ex}}$ is the CO₂ imports induced by exports.

Unlike the domestic consumption of CO₂ of (3), the domestic production of CO₂ is only determined by the emission factors of own country as

$$(6) \mathbf{z}_a^{\text{DP}} = \mathbf{e}_a (\mathbf{I} - \mathbf{A}_a^{\text{D}})^{-1} (\mathbf{f}_a + \mathbf{f}_a^{\text{ex}}) + e^{\text{fd}} \mathbf{f}_a$$

The CO₂ embodied in imports \mathbf{z}_a^{IM} is the emissions regarding the comparative imports, non-comparative imports and re-export and written as

$$(7) \mathbf{z}_a^{\text{IM}} = \sum_{\beta}^{\text{W}} \mathbf{e}_{\beta}^* \left[(\mathbf{A}_{\alpha,\beta}^{\text{M}} (\mathbf{I} - \mathbf{A}_a^{\text{D}})^{-1} (\mathbf{f}_a + \mathbf{f}_a^{\text{ex}}) + \mathbf{nm}_{\alpha,\beta} + \mathbf{f}_{\alpha,\beta}^{\text{rx}} \right]$$

From (3), (5), (6) and (7), the difference of emissions embodied in exports and imports is equivalent to the difference of consumption-based emissions (excluding the direct emissions of final consumption) and production-based emissions.

The net CO₂ emissions embodied in international trade is given as

$$\mathbf{z}_a^{\text{EX}} - \mathbf{z}_a^{\text{IM}} = \mathbf{z}_a^{\text{DP}} - \mathbf{z}_a^{\text{DC}} = \mathbf{e}_a (\mathbf{I} - \mathbf{A}_a^{\text{D}})^{-1} \mathbf{f}_a^{\text{ex}} - \sum_{\beta}^{\text{W}} \mathbf{e}_{\beta}^* \left[(\mathbf{A}_{\alpha,\beta}^{\text{M}} (\mathbf{I} - \mathbf{A}_a^{\text{D}})^{-1} \mathbf{f}_a + \mathbf{nm}_{\alpha,\beta} \right].$$

3. DATA

3.1 Availability overview

Obviously, the accuracy of the calculation results depends heavily on the number, comparability, and limitations of available country databases for production and trade structures. One of the major challenges of a multinational carbon-embodiment analysis is the provision of an internationally-harmonised economic database. The sector classifications and database format of original published-data sources unfortunately vary across countries (Table 2).

Using the international harmonised database estimated by the OECD, this study has succeeded in increasing the country coverage to 41 countries/regions. The sector classifications of OECD Input-Output, STAN Bilateral trade database (BTD) and the IEA CO₂ Emissions from Fuel Combustion are basically formatted and harmonised in the sector classification of ISIC Rev.3. Although more detailed sectors are available for OECD I-O and BTD, the 17 aggregated sectors (Table 3) are used in this study mainly due to the limitations of detailed industry of emissions database.¹ The rest of this section provides descriptions of each data source and its limitations, adjustment procedures and of some indicators calculated using the collected database.

1. See Table A1 for the sector concordance table across data sources. The detailed sector analysis certainly needs to be undertaken in future extensions to the present work. Some single-country studies produced analysis at relatively detailed sectoral resolutions.

Table 2. Existing data sources for intercountry CO₂ transfer analysis

	CO ₂ Emissions	Input-Output	Bilateral Trade	
			Goods	Services
Sources	IEA	National Statistics Offices	OECD, UN, Eurostat	OECD, UN, Eurostat
Sector details	Not as detailed as I-O and BTD	Good (except for a few countries)	Very detailed.	No detailed information available for most
Sector classification	ISIC	Various classifications (Industry and Products)	HS, SITC (not harmonised with industry and product class.)	BoP, EBOPS (not harmonised with industry and product class.)
Year	Good	Recent years not available	Good	Only available for years after 2000
Country coverage	Good	Good	Good	Poor
International comparability	Good	Various formats	Various mirror statistics problems (re-export, fob/cif, origin/destination differences)

6 Paper, paper products, printing & publishing	21+22	16 Transport and storage	60-63
7 Chemicals and chemical products	24	17 All other services	50-55,64-99
8 Other non-metallic mineral products	26		
9 Iron and Steel	271+2731		
10 Non-ferrous metals	272+2732		

Input-Output tables

The key variables of this analysis, such as input-output coefficient matrices of domestic and imported products, domestic final demand on domestically-produced goods, domestic final demand on total imported goods, and exports, are given by national input-output tables.

The latest edition of the OECD Input-Output database (2006 edition Rev.1) covers the domestic and import transaction tables of 38 countries for the mid-1990s and the early-2000s (Table 4). The global GDP coverage is about 90% (in USD) and the population coverage is 67% for 2000 (Yamano and Ahmad, 2006).

Among our target 41 countries/regions, tables for five countries/regions (Hong Kong, Iceland, Mexico, OPEC, and the rest of the world) were not available for either 1995 or 2000. Alternate tables for these countries/regions were thus chosen in order to approximate their production structures. The selection criteria for choosing alternate tables were similarities in production and trade structures, such as share of manufacturing sectors, import share of manufacturing goods, and import trade partners. The alternate input-output coefficients are selected from Singapore for Hong Kong, from Norway for Iceland, from the

United States for Mexico, from Indonesia for OPEC and from Indonesia for the rest of the world. The final components were accordingly modified by the ratio of GDP between countries and by the alternate country's final demand structures.

Even for the 17 aggregated sectors, there are various restrictions on a number of sectors. The non-ferrous metals cannot be separated from the rest of basic metals (ISIC Rev.3, 27) for most European countries,² Canada, China, New Zealand, and the United States. For Russia, the following sectors are also merged in our analysis: 1) Wood, wood products and cork (ISIC Rev.3, 20) and Paper, paper products, printing (ISIC Rev.3, 21-22); 2) Fabricated metal products, machinery and equipment (ISIC Rev.3, 28-32), and Transport equipment (ISIC Rev.3, 34-35).

Further adjustment procedures were required to calculate the proper input-output coefficients for the tables, in which the transactions of scrap and by-products were recorded as negative values. For example, the Japanese table for 1995 is compiled by the Stone procedure and the table for 2000 is compiled through the Reuse-Recycling procedure. Using separately-published scrap and by-product satellite tables, the original I-O tables have been converted to transfer-type tables in which negative values are removed from the intermediate transactions.

1994/5 is the fiscal year of 1994-95.

Currency conversion rates

In order to harmonise the currency unit of national input-output tables with US dollar-based trade statistics, the national tables are depreciated by currency exchange rates. The annual market currency exchange rates are from OECD Annual National Accounts for OECD members, Brazil, China, India, Indonesia, Russia, and South Africa; National Income Data, National Statistics, Republic of China for Chinese Taipei; and International Financial Statistics, IMF for other countries.

In many countries, the nominal growth rates based on the national currency decreased in the US dollar-based figures, as the exchange rate to USD relatively appreciated for 31 countries in 1995 and 2000 (Table 5). Significant changes in the currency exchange rates in the late 1990s are observed in Turkey

2. Austria, Belgium, Czech Republic, Denmark, Greece, Finland, France, Hungary, Ireland, Italy, Luxembourg, Netherlands, Norway, Poland, Portugal, Slovak Republic, Spain, Switzerland, Sweden, and United Kingdom.

(78.9%/year), Russia (43.8%/year), Indonesia (30.2%/year), Brazil (12.7%/year), Poland (12.4%/year), Philippines (11.4%/year), and South Africa (11.4%/year).

The official rate published by EU commissions is used for EURO zone countries.

Trade data

Using the import partner shares of the bilateral trade data in goods, the import transaction table in the I-O tables can be separated into the corresponding trade partners. The sector classification of OECD STAN Bilateral Trade Data (BTD) is based on ISIC Rev.3, similar to the OECD Input-Output database.³ The trade transactions not covered by BTD are supplemented by the detailed HS-based data source of OECD ITCS and UN Comtrade for Argentina, Malaysia, Philippines, Singapore, OPEC⁴ and the rest of the world. For I-O-unavailable countries, the export columns of alternate countries' export series are also adjusted by the bilateral trade data sources (*i.e.* BTD, OECD ITCS, and UN Comtrade).

Ideally, to link national I-O tables in order to carry out inter-country analysis requires a consistent set of harmonised international trade, accounting for mirror statistics issues in exports and imports, including adjusted re-exports and uniform definitions of origin and destination countries. Although these statistical issues have been discussed for many years, none of the existing data sources, however, provide "the harmonised" dataset yet. The compilations of the harmonised trade statistics is an issue remaining to be solved for future research to progress (Guo *et al.*, 2009).

3. See Guo *et al.* (2009), for the limitations of currently available data sources of bilateral trade data in goods and services.
4. Algeria, Islamic Republic of Iran, Kuwait, Nigeria, Qatar, Saudi Arabia and Venezuela for 2000. Algeria, Saudi Arabia and Venezuela for 1995.

CO₂ emissions by industry sector

The sector classification of the IEA's CO₂ Emissions from Fuel Combustion data is also based on ISIC Rev. 3. The emissions of transport activity are prorated to each sector by the share of petroleum inputs of I-O tables. The emissions from unallocated auto-producers of electricity are also allocated to the following 4 sectors on the basis of petroleum inputs calculated in the I-O tables: Mining, quarrying and petroleum refining (sector 2), Chemicals and chemical products (sector 7), Iron and steel (sector 9), and Non-ferrous metals (sector 10).

3.2 CO₂ emission factors by sector

A CO₂ emission factor, the average unit of CO₂ emitted per unit of sectoral output, is simply calculated by dividing CO₂ emissions⁵ by output for each sector. The CO₂ emission factor of the utility sector is a primary source of CO₂ emissions in most countries.⁶ Yet, the direct emissions factors of the utility sector vary greatly across countries due to the different power generation systems used (Figure 4).

For example, the direct emission factors of the utility sector are relatively low in Brazil, France, Iceland, Norway and Switzerland where the majority of electricity is supplied by non-thermal power generations (*i.e.* hydro and nuclear). On the other hand, the emission factors are significantly high in some eastern European countries and major non-OECD countries such as China, India, and Russia where coal-fired fuels are the primary source of power generation.

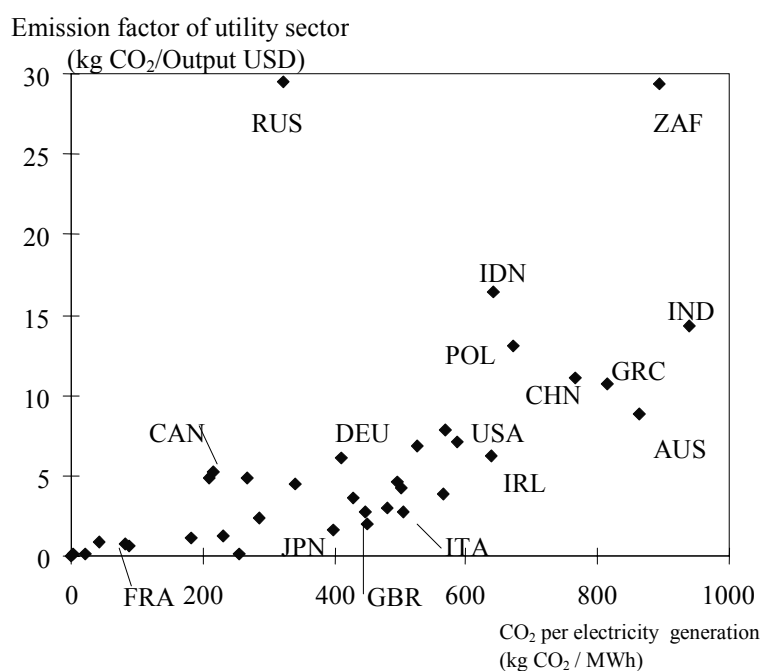

The country deviations of emission factors for other sectors are much smaller than the utility sector (Table A. 2 and Table A.3) and the relative order by sectors is basically stable between 1995 and 2000. The following are generally highly carbon-intensive sectors in the target countries: (2) Mining, quarrying and petroleum refining, (7) Chemicals and chemical products, (8) Other non-metallic mineral products, (9) Iron and Steel, and (14) Utility.

Note that changes in the emission factors are also affected by the denominator, *i.e.* the US dollar-based sectoral output. For example, the emission factor of the electricity sector of Japan has increased from 1.403 kg CO₂ /USD to 1.637 kg CO₂/USD from 1995-2000, as has the currency exchange rate over the same period (94.1 Yen/USD in 1995 to 107.8 Yen/USD in 2000). So the "unimproved" Japanese emission factors are mainly due to the changes in the currency exchange rate. However, among the 30 countries where the USD-based emission factors increased, the indices in national currency increased in only 11 of the countries (*e.g.* Russia and India).

For the I-O unavailable countries, the emission factors of alternate countries are used, such as Singapore for Hong-Kong, Denmark for Iceland, Brazil for Mexico, Indonesia for OPEC and Indonesia for the rest of the world. However, for the utility sector, the emission factors of neighbour countries are adjusted by the mix of generation techniques (kg CO₂/MWh).

5. IEA's CO₂ Emissions from Fuel Combustion is based on the IPCC Tier 1 Sectoral Approach. The database only includes the emissions from fuel combustion. The other sources of global warming factors are not covered *e.g.* the industrial processes of chemical reactions and waste combustion.

6. The emission from public electricity and heat production is about 35% of sectoral approach total in 2002 for OECD average and it has been constantly increasing in the last 30 years.

Figure 4. Emission factor of utility sector vs. unit emissions per power generation (2000)

Sources: IEA, OECD.

3.3 Production and trade structure

The target countries obviously increased their foreign dependencies in the late 1990s (Table 6 and Table 7). The ratios of imports to GDP have increased in 29 countries, while the ratios of export to GDP have increased in all target countries except for France and Norway.

The sectorally-aggregated output and trade figures show significant increases in highly carbon-intensive sectors such as (2) Mining, quarrying and petroleum refining, (7) Chemicals and chemical products, (8) Other non-metallic mineral products, (9) Iron and Steel, and (14) Utility, increases which were greater in non-OECD countries where the direct emission factors are larger than in the OECD countries. The increases in trade volumes of carbon-intensive products imply that the apparent increases in international carbon embodiments took place.

Note that the changes in these tables are also affected by movements in currency exchange rates measured against the key currency (US dollar). The nominal GDP in 15 countries thus decreased in the late 1990s, but this is not generally due to economic recessions.

Table 6. Exports by sectors (Billion USD, current exchange rate based)

4. MEASUREMENT RESULTS OF CO₂ EMISSIONS EMBODIMENT IN INTERNATIONAL TRADE

4.1 Cases

This section provides the calculation results of carbon embodiment using the data sources described in previous section. In addition to a base case scenario which is based on the actual trade patterns and energy efficiencies, two sensitivity analyses are also calculated: (1) changes in trade patterns, and (2) changes in carbon emission factors. Due to the complex interdependent production processes among countries, the impacts on marginal changes in energy efficiency and trade patterns are difficult to predict without numerical simulation.

Note that the final expenditures and investments *i.e.* final demand components are fixed at the same levels of actual numbers in order to compare the marginal effects of changes in trade patterns and carbon intensities. In other words, any investments and expenditures required to expand the capacity of trade infrastructures or to install less-carbon-intensive production facilities are not taken into account in these numerical examples.

4.2 Major findings: Base case

The worldwide CO₂ emissions generated to satisfy domestic demand in the OECD countries (hereafter consumption-based CO₂ emissions) amounted to 14 037 Mt CO₂ of CO₂ emissions, which was 16.1% (1 949 Mt CO₂) higher than the 12 088 Mt of CO₂ emissions generated by production within the OECD in 2000 (Table 8). The increases in the consumption-based emissions in the late 1990s are significant in the following seven countries: United States (1 075 Mt CO₂), India (177 Mt CO₂), United Kingdom (99 Mt CO₂), Canada (95 Mt CO₂), Japan (94 Mt CO₂), Brazil (73 Mt CO₂), and China (71 Mt CO₂).

The net importer and net exporters are clearly separated by OECD and non-OECD members. The six largest OECD countries accounted for 91% of the total carbon trade deficit of OECD (-1 949 Mt CO₂) in 2000: United States (-858 Mt CO₂), Japan (-312 Mt CO₂), United Kingdom (-196 Mt CO₂), Germany (-147 Mt CO₂), France (-134 Mt CO₂) and Italy (-127 Mt CO₂). On the other hand, large carbon trade surpluses are observed in five major non-OECD countries: Russia (586 Mt CO₂), China (387 Mt CO₂), Indonesia (64 Mt CO₂), India (56 Mt CO₂) and South Africa (55 Mt CO₂). The consumption-based emissions also exceed the production-based emissions in other 16 OECD countries.

The country orders of embodied emissions can also be evaluated by GDP-normalised (OECD Main Economic Indicators for PPP based GDP) and per capita figures (Figure 5 and Figure 6). The larger net imports in terms of GDP normalised emissions are found in Singapore, Portugal, Switzerland, Luxembourg, and Sweden in 2000. On the other hand, Russia, South Africa and Czech Republic are larger net-exporter countries.

For most OECD countries, as the rate of increase for GDP is greater than the rate of increase for CO₂ emissions, the emissions per unit of production have therefore decreased in most countries (only six countries increased in 1995-2000). On the other hand, per capita emissions still increased in most OECD

countries (19 countries) in the late 1990s (Figure 6). The OECD average increased by 8.9% in the late 1990s. The relatively high increases are measured for Canada (18.2%), New Zealand (19.5%), Portugal (20.6%), and Spain (17.7%). The per capita emissions of non-OECD countries however have slightly decreased (-2.8%). This is mainly due to the improvement in carbon intensity in two-highly populated countries (Russia and China) although the significant increases are observed in Brazil (19.8%) and India (16.7%).

An index for discrepancies of per capita consumption-based emissions across countries (standard deviation) increased while the disparities remained the same in production-based emissions.⁷ In the late 1990s, the population growth, production and electricity generation techniques in each country also remained relatively more stable than changes in consumption-based emissions. This implies that the changes in gaps between consumption-based emissions and production-based emissions are mainly due to the changes in the trade patterns rather than the changes in other factors.

7. Standard deviation of per capita consumption-based emissions has increased from 4.9 in 1995 to 5.4 in 2000 while this index for production-based emissions remained around 4.5.

**Figure 5. Production and consumption-based emissions per GDP
(base case, 2000, CO₂ tons / USD)**

**Figure 6. Per capita consumption-based emissions of 1995 and 2000
(base case)**

Notes: The OECD figure here does not include Iceland and Mexico. Non-OECD does not include Rest of the world.

The input-output approach is also eligible to show the detailed sector information of CO₂ emission contents for each sector (Table A. 4 and Table A. 5). Since electricity is the most carbon-intensive of the intermediate goods, the CO₂ contents of each country's products are highly correlated to the direct emission factors of the utility sector. Figure 7 and Figure 8 detail the CO₂ emissions contained in the food products, beverages and tobacco sector and fabricated metal products and machinery sector respectively.

Figure 7. Embodied emissions per production: Food products, beverages and tobacco (base case, CO₂/USD)

Figure 8. Embodied emissions per production: Fabricated metal products and machinery (base case, CO₂/USD)

4.3 Major findings: Sensitivity analysis

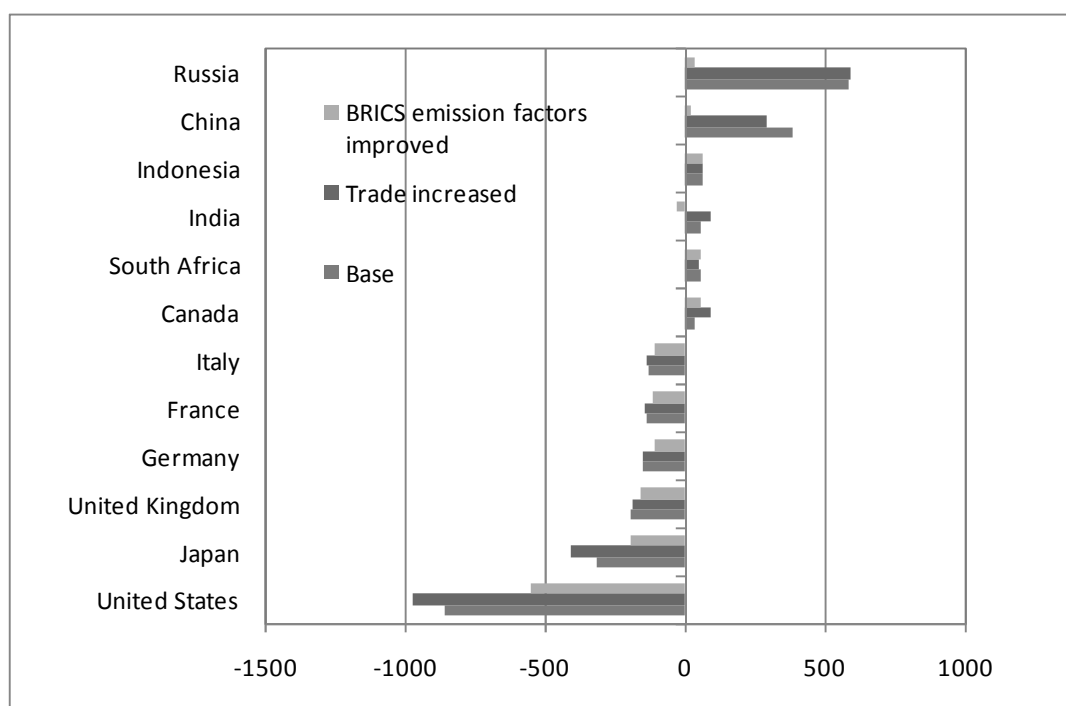

The first-simulation case measures the impacts of further global procurement processes. Under this sensitivity analysis, the import coefficient of each country is increased by 5%, the exports of partner countries are simultaneously inflated by 5%. The gap between consumption-based and production-based emissions becomes wider in the large CO₂ deficit countries (e.g. United States and Japan) and the large CO₂ surplus countries (e.g. Russia, India and Canada).

The Chinese carbon trade surplus of the base case, however, is reduced by the changes in trade intensities. The impact is different from other major non-OECD countries such as Russia, India, Indonesia and South Africa. The increase in purchases of high-carbon content Chinese products by her partner countries certainly increases the emissions embodied in exports. In the past decade, however, China

became a net-importing country of petroleum. This implies that the current Chinese economy requires an increase in the CO₂ emissions embodied in petroleum imports in order to satisfy increased domestic and foreign demands of their products. Thus, the Chinese net exported emission of base case scenario has decreased from 387 Mt CO₂ to 294 Mt CO₂ in this numerical example. Our simulation results imply that the impacts of changes in trade structure are difficult to predict *a priori* and large impacts are estimated for some countries (e.g. China, India, Canada, Japan and United States in Figure 9).

The second sensitivity analysis estimates the impacts of diffusion of OECD's technology and structure to the BRIC countries (Brazil, Russia, India and China). Since the BRIC countries are major emitters and have higher direct emission factors than most of the OECD countries, the global emission level for 2000 is reduced from the 22 171 Mt CO₂ of the base case to 19 151 Mt CO₂. The consumption-based emissions in OECD countries also decreased as a result of reduced emissions embodied in imports. The trade balances disparities between OECD countries and non-OECD countries are significantly reduced (Figure 9).

Figure 9. Differences in consumption and production-based emissions for major OECD and non-OECD countries (consumption – production, Mt CO₂, 2000)

Notes: The detailed results are available at Table A. 8 - Table A. 11.

5. SUMMARY

Despite the various limitations on data sources, a number of potentially significant results are obtained from our calculations and simulations using our interlinked input-output based model. The results derived for emissions embodied by sector and by country are highly valuable for post-Kyoto policy discussions on GHG mitigation. The main results concerning the carbon emissions embodied in international trade include the following:

- The consumption-based CO₂ emission of the OECD overall was 16.1% higher in 2000 than the conventional measurement of production-based emissions suggests. Those differences exceed 30% in seven OECD countries (Austria, France, Luxembourg, Portugal, Sweden, Switzerland, and United Kingdom). As expected, the magnitude of differences increased in the late 1990s due to the increased trade in goods and services.
- Growth of trade-adjusted consumption-based CO₂ emissions has not decelerated as much as has the growth of domestic CO₂ emissions in OECD countries, partly reflecting global relocation of emissions-intensive activity towards non-OECD [or non-Annex I] countries. While less than half of the global increase in CO₂ emissions in the late 1990s took place within the OECD economies, two-thirds of the global increase is still attributable to OECD consumption.
- Our sensitivity analysis results imply that the recent globalisation of industrial activity has had a significant impact on the discrepancies between production and consumption-based emission measures.
- Thus, future international discussions on carbon mitigation programme may need to consider not only individual countries' territorial emissions (as in the Kyoto Protocol approach) but also consider how CO₂ emissions are embodied within the trade among a broader set of target countries, according to a consumption-based measurement approach such as the one explored here.
